INTRODUCTION

The present specifications (1) for the design of shear connectors in composite steel-concrete bridge members are based on the static properties of the connectors. (2) Hence, they note only that in the negative moment regions of continuous beams the slab reinforcement may be considered as contributing to the moment resisting capacity of a section if connectors are used. If connectors are provided only in the positive moment regions the specifications require that the steel beams be designed to resist the full negative moment.
Since design procedures based on the static properties of connectors have led to very conservative designs, no apparent difficulties have been encountered. In fact, fatigue tests of simple beams which were designed using the criterion suggested in Ref. 1 have shown that adequate connector fatigue strength is available. The same was also assumed to be true for continuous beams. Because bridge engineers have recognized that such a design procedure is conservative the factor of safety has been reduced in the present specifications(1). However, a recent study (3) has shown that it is not possible to arbitrarily reduce the factor of safety because the fatigue behavior may then become critical. Due to this apparent divergence in views, it was considered desirable to evaluate the performance of continuous composite beams with shear connectors proportioned using the design procedures suggested in Ref. 3. The design criteria used in Ref. 3 was based on the results of previous fatigue tests of simple span composite beams (4,5,6) and on a fatigue test program which involved several factorial experiments on stud and channel shear connectors. In addition, both the fatigue and static behavior required further study and evaluation to determine the applicability of the suggested design procedures for continuous composite bridge members(3).
All previous studies on continuous composite beams have evaluated only their static behavior. Viest, Fountain, and Siess (2) discussed the negative moment regions of continuous composite beams in some detail. Their discussion was based on the static behavior of two composite model bridges reported by Siess and Viest (7). These two models differed in that one had shear connectors throughout the beam while the second had shear connectors in the positive moment regions only. They concluded that (1) in the negative moment regions only the longitudinal slab reinforcement can act compositely with the steel beam, (2) where shear connectors are used throughout a beam the longitudinal slab reinforcement is fully effective; when connectors are omitted from the negative moment region the slab reinforcement is only partly effective, (3) the action of both continuous composite model bridges was about the same since the distribution of strains and thus also of moments in both the positive and negative moment regions was nearly the same. They also concluded that the use of an elastic analysis in combination with the usual load distribution factors is justified, and that no special provisions are needed for the design of continuous composite bridges (2).

Slutter and Driscoll (9) summarized the behavior of a single continuous composite beam tested statically to its ultimate load. They noted that the theoretical plastic collapse
load was exceeded in the test even though the beam had inadequate shear connection throughout its length.

Barnard and Johnson (10) presented the results of a study on the plastic behavior of continuous composite beams. These preliminary studies were followed up by further studies designed to provide more information on secondary failures (11). In particular, the effects of cracking and transverse bending of the slab on the plastic behavior and the behavior of the longitudinal reinforcement in the negative moment regions were examined, but under static ultimate loads.

To provide experimental data on the fatigue strength of continuous composite beams having stud shear connectors in the negative moment region, comparative laboratory fatigue tests were conducted at Lehigh University on four full size two-span continuous composite beams. Two of the beams were identical except that one had connectors in the negative moment region while the other did not as is common practice in current designs. Both test beams had identical longitudinal and transverse reinforcement. The amount of reinforcement provided was made equal to that required by the present specifications (2,8) for a bridge deck of similar proportions and subjected to H20-S16 truck loading. The other two continuous composite beams were similar to the first pair but had connectors throughout their length in
addition to substantially more longitudinal reinforcement through their negative moment regions. This paper presents the results of the fatigue test program.

After the fatigue test program was completed, all four continuous composite beams were tested statically to their ultimate load capacity. The results of the static tests of these beams are reported in Ref. 12.

DESCRIPTION OF TEST BEAMS, INSTRUMENTATION AND TEST PROCEDURE

Each of the four continuous composite beams which was fatigue tested was 50 ft. long and had two equal spans of 25 ft. between supports. Symmetrical concentrated pulsating loads, distributed transversely across the slab width, were placed 10 ft. from the exterior supports in each span. Each beam consisted of a reinforced concrete slab 60 in. wide and 6 in. thick connected to a 21W62 steel beam by pairs of 3/4 in. x 4 in. headed steel stud shear connectors. The transverse spacing of studs in each stud pair was 4 inches. The rolled beams were all supplied from the same heat of A36 steel. The four test beams were designated CC-1F, CC-2F, CC-3S, and CC-4S. Details of the test beams are shown in Figs. 1 and 2.

Design Criteria

The composite beams were designed according to the transformed moment of inertia method by transforming the concrete slab to
Daniels, Fisher

an equivalent area of steel in the positive moment regions using an assumed modular ratio of 10. The longitudinal reinforcing steel was considered in both the positive and negative moment regions. For purposes of this paper the dead load point of inflection will define the positive and negative moment regions. Table 1 summarizes the resulting design stresses for the composite beams. A small spreading of shear connectors was made over the interior support of beam CC-2F so that the tensile stress in the beam flange adjacent to a stud shear connector did not exceed the specification value (1).

The longitudinal and transverse reinforcement for beams CC-1F and CC-2F was designed in accordance with the AASHO Bridge Specification (1). The transverse reinforcing steel was designed assuming that an H20-S16 truck was placed on a 6 in. deck spanning 5 ft. center-to-center of the steel beams. The longitudinal distribution reinforcement was made continuous and was taken as 0.67 percent of the required transverse reinforcement. The reinforcement for beams CC-3S and CC-4S was essentially the same except that the amount of transverse reinforcement was reduced by nearly one half and the amount of longitudinal reinforcement through the negative moment regions was substantially increased. The longitudinal reinforcement in the positive moment regions of these two beams (except adjacent to the negative moment region) was the same as in beams CC-1F and CC-2F. In CC-4S, the longitudinal reinforcement in the negative
moment region was determined on the basis that the ultimate moment capacities of cross-sections in the positive and negative moment regions would be nearly equal, using handbook properties. In beam CC-3S, the longitudinal reinforcement in the negative moment region was determined so that the ultimate moment capacity would be about midway between that for beams CC-2F and CC-4S.

The shear connectors in all four test beams were designed according to either the fatigue or static criteria proposed in Ref. 3. For beams CC-1F and CC-2F, the connectors were proportioned to sustain a fatigue loading to 2,000,000 cycles of zero to maximum load application (zero stress ratio). The two beams differed only in that connectors were not provided in the negative moment region of beam CC-1F. For beams CC-3S and CC-4S, the connectors were proportioned on the basis of the static strength requirements but were subjected to 500,000 cycles of zero to maximum load application. Consequently, only a certain number of the connectors in beams CC-3S and CC-4S were subjected to a range of shear near the value suggested in Refs. 1 and 3. Table 1 shows the expected forces on the shear connectors and indicates the critical regions in beams CC-3S and CC-4S.

Design Details and Fabrication

The details of the steel beams and connectors are shown in Fig. 3. Each of the four beams was cut from nominal
length 57 ft. rolled sections. The excess pieces were de­
Iivered to the laboratory after all shear connectors were in­
stalled to provide material for tension tests of the steel
section and studs. The bearing stiffeners at the center sup­
ports of CC-1F and CC-2F were designed short to eliminate
welds near the region of high tensile stresses. Web stiff­
eners and additional short bearing plates in the region of
the center supports of beams CC-3S and CC-4S were installed
in the laboratory to stiffen that region and to prevent pre­
mature failure of the beams during the static ultimate load
tests.

All studs were placed in pairs except in the nega­
tive moment region of beam CC-2F where single studs were stag­
gered as shown in Fig. 3. Before the studs were welded to the
test beams, the welding equipment was calibrated by welding
several studs to the excess lengths that were cut off. The
quality of the welds was verified using the welding and in­
spection procedure outlined in Ref. 13. Two different lots of
studs, supplied by two manufacturers, were installed. Beams
CC-1F and CC-4S had lot A studs, and beams CC-2F and CC-3S had
lot B studs. This choice was random.

The placement of reinforcing bars is shown in Figs. 1
and 2. The lapped No. 4 bars in CC-1F and CC-2F were welded to
provide continuous longitudinal reinforcement throughout. No welding was done in beams CC-3S and CC-4S.

The transverse reinforcement in all beams was provided by No. 5 bars bent into rectangular hoops. In beams CC-1F and CC-2F, these bars were placed on 6 in. centers throughout the beam. For beams CC-3S and CC-4S, a variable spacing was used as indicated in Fig. 1. The crack patterns and test results for beams CC-1F and CC-2F indicated that it was not necessary to provide such a large amount of transverse reinforcing steel in most of the positive and negative moment regions since longitudinal cracking of the slab was not a factor. However, a closer spacing was used under the load points and at the center support to provide for cross bending of the slab at these points.

Construction

Construction of the continuous composite T-beams began with the erection of a pair of the steel beams on supports bolted to the dynamic test bed in the laboratory. The beams were spaced 5 ft. 2 in. apart and clamped to the supports. Plywood forms for the slabs of the two T-beams were suspended from the beams. A two-inch timber spacer was used to separate the slabs of the two T-beams along their length.

The slabs were made with transit-mixed concrete proportioned for a 28-day compressive strength of 3000 psi.
Beams CC-1F and CC-2F were constructed first. The concrete placement for these two beams began simultaneously at the exterior supports of each span and progressed toward the interior supports. Placement was stopped 6 ft. on either side of the interior supports. The remaining 12 ft. was placed a week later to allow time for installation of strain gages on the reinforcement in that region. Beams CC-3S and CC-4S were constructed later and the concrete placement began at one exterior support and progressed to the other end. Consolidation was accomplished by internal vibration along the slab as placement progressed. The final finish was obtained by hand troweling. From 16 to 32 test cyclinders were poured with each placement.

The concrete in the slabs of all beams was moist-cured for seven days with the exposed surface covered with wet burlap and a polyethylene sheet. The forms for each pair of test specimens were removed approximately 14 days after casting, then the specimens were allowed to cure under dry conditions for at least 14 days.

The mechanical properties of the structural steel beams were determined from tests of tensile coupons cut from a 2 ft. piece of the beam that had been flame cut from the original 57 ft. length. The coupons were tested in tension at a speed of 0.025 in. per minute up to the onset of strain.
hardening and then at a speed of 0.50 in. per minute to fracture. The mean values and standard deviation of the yield point, static yield stress, and the ultimate strength are listed in Table 2. Values of the modulus of elasticity and the strain hardening modulus are also given.

The mechanical properties of the Nos. 4, 6, and 7 deformed longitudinal reinforcing bars were determined by tension tests of 3 ft. lengths of reinforcement. The deformed bars were of intermediate grade steel conforming to ASTM A15. The average yield points and ultimate strengths are also given in Table 2.

The properties of the studs were determined from tensile tests on full-size studs. The average yield points and ultimate strengths are also summarized in Table 2.

The concrete placed in the slabs of all four beams was made of Type 1 portland cement, crushed gravel and natural bank sand. The standard 6 in. by 12 in. cylinders poured during slab casting were tested at 28 days and at the beginning of each fatigue test. The 28-day cylinders were moist cured. The other cylinders were cured under approximately the same curing conditions as the slabs. The compressive strengths, splitting strengths and moduli of elasticity are given in Table 3.
Actual Cross-Section Properties

The section properties of the composite sections in the positive moment regions were computed assuming that the effective width of the slab was the full 5 ft. width, and that the modulus of elasticity of the concrete was equal to that determined from the 28-day cylinder tests. The section properties of the composite sections in the negative moment regions were computed based on the steel beam and the longitudinal reinforcing steel. It was assumed that the concrete slab was cracked throughout. Table 4 gives the values of the moments of inertia and the distance of the neutral axis from the bottom of the beam for each test beam.

Instrumentation

The instrumentation for beams CC-1F and CC-2F was essentially the same. The instrumentation for beams CC-3S and CC-4S was also essentially the same but differed from that for the first two beams. A combination of electrical resistance strain gages, dial gages and level bars was used.

Figures 4 and 5 show the location of the strain gages. Figure 4 shows the location of the strain gages used to determine the flexural strains in the steel beams and in the concrete slabs. These gages were used to ascertain the transverse distribution of the strain during the fatigue test. Strain gages were also
attached to the top surface of all the longitudinal No. 4 bars at the cross-section containing the interior support.

Figure 5(a) shows the location of the studs which had strain gages mounted under them on the bottom of the top flange. Figure 5(b) shows the placement of these gages relative to a stud. The strain gage is not placed directly under a stud but offset slightly in the direction of the expected shear force on the stud. No significance is attached to the absolute magnitude of measured strain. However relative values of measured strain serve to indicate the relative magnitudes of the shear force being transmitted by the stud above the strain gage. Their use and development is discussed further in detail in Refs. 4 and 5.

Dial gages (0.001 in.) were placed under the beams at the load points to measure vertical deflection. These gage readings were used to adjust the maximum dynamic load level at the beginning and throughout the duration of each beam test. Dial gages (0.001 in.) were also used to measure slip at each end of the beams and at various sections along the beam spans.

For beams CC-3S and CC-4S, a large compression dynamometer was used at the interior support to measure the center reaction. This reaction was used together with the known loads to determine bending moments along the beam. A check was thus
provided on the bending moments computed from the strain measurements on the steel beam.

A 40 power microscope was used to measure the width of cracks in the slab in the negative moment region of CC-3S. Crack widths during the other three beam tests were estimated. In addition, the crack patterns were photographed following each beam test.

Test Procedure

A pulsating concentrated load was applied simultaneously to each span by hydraulic jacks. The loading rate was constant for all beams at 250 cycles of zero to maximum load per minute. The test set-ups are shown schematically in Fig. 6. The interior support of CC-1F and CC-2F consisted of a bearing plate free to rotate on a fixed support assembly. Longitudinal and lateral stability was thus provided at this point. For beams CC-3S and CC-4S the interior support was replaced by a bearing plate resting on a compression dynamometer, which provided no longitudinal or lateral stability to the beam. A supplementary support assembly was therefore used to provide horizontal support at this point.

Fatigue testing of beams CC-1F, CC-2F, CC-3S, and CC-4S was started 35, 71, 39, and 45 days respectively, after
the concrete slabs were cast. Prior to any fatigue loading, each beam was loaded once, statically, to the maximum load to be applied during the fatigue test. This load was applied in increments of 10 kips up to a maximum of 60 kips at each load point for beams CC-1F, CC-2F, and CC-3S and up to 70 kips for beam CC-4S. Readings were taken from all the gages at each load increment.

The maximum dynamic load to be applied during the fatigue tests was controlled by the deflections obtained under the first static load test and under additional static load tests performed at frequent intervals. During the initial stages of each fatigue test the dynamic deflections of each span could not be made simultaneously equal to the corresponding controlling static deflections. In this case the dynamic load was taken such that the smaller dynamic deflection under one of the two load points was equal to the corresponding controlling static deflection. The dynamic deflection at the other load point was therefore in excess of its controlling static deflection during the increment of applied cycles of fatigue loading. However, the controlling static deflections, corresponding to equal maximum static loads, also increased rapidly during the initial stages of each test due to bond failure between slab and beam as well as other causes. Therefore the procedure followed was not considered unconservative.
The maximum dynamic load was always less than the maximum static load because of the dynamic effect. For beams CC-1F and CC-2F the dynamic load correction was usually from 1 to 2.5 kips at each load point. In all the beam tests the higher value was associated with the initial 10 to 20% of the total number of cycles applied to the beam, except for beam CC-1F where a value of 6.5 kips was reached midway through the test.

The minimum dynamic load varied from 3.5 to 7.5 kips for beams CC-1F and CC-2F and from 2.0 to 4.0 kips for beams CC-3S and CC-4S. In this case, the lower values tended to be associated with the initial stages of the test. The minimum load was the smallest that could be applied without separation of the beam and loading jack throughout the fatigue testing period.

It was apparent that connectors were failing in beam CC-1F after 500,000 cycles of load application. This was more serious in the east span where the resulting loss of stiffness caused a large difference in the deflections of the two spans at approximately 1,100,000 cycles. If the fatigue test of beam CC-1F was to continue to 2,000,000 cycles some means of preventing the large differences in stiffness between the two spans was necessary. Therefore a clamp was installed in the
east span approximately at the inflection point so that greater frictional resistance could be developed between the slab and the steel beam. The clamp consisted of two steel plates which were welded to the underside of the top flange of the steel beam on opposite sides of the web and then bolted through the slab to another steel plate on the top of the slab. Even with this reinforcement, the fatigue test of beam CC-1F was stopped short of 2,000,000 cycles of load application due to accelerated failures of connectors in the west span. The clamp was installed at 1,074,900 cycles and removed at 1,375,500 cycles after deflections in both spans had again stabilized.

After completion of each fatigue test, the continuous beam was tested to its static ultimate strength (12). After the static strength test was completed, the concrete slab was then removed from the steel beam in the vicinity of the exterior supports, throughout the negative moment region, and from the positive moment regions near the points of contraflexure. Photographs were then taken of the connector failures and cracked connectors. Also, each connector in these regions was bent at least 45° with a sledge to ascertain whether fatigue cracks were present. Several connectors fractured during this process. The visual inspection and bending test was used as a verification of the information obtained from the electrical resistance strain gages placed under the
the studs as follows: (1) If a connector was seen to be completely fractured when the steel beam was exposed or was removed during the 45° bending test, its strain-cycle curve (Fig. 12 for example) was examined to ascertain its cycle life. The number of cycles corresponding to a sharp reduction in strain reading was taken as the cycle life of the connector (4,5). (2) If a connector did not fracture from the flange during the bending test but a fatigue crack was visually present, its cycle life was taken as the total number of cycles applied to the specimen. (3) If a connector did not fracture and if no fatigue cracks were visible its cycle life was considered greater than the total number of cycles applied to the specimen.

TEST RESULTS

Each continuous composite beam except CC-1F was subjected to at least the desired amount of cyclic loading. 1,906,900 cycles of load were applied to beam CC-1F and 2,079,000 cycles of load were applied to beam CC-2F. Beams CC-3S and CC-4S each had 500,000 cycles of load applied. As previously stated, it was observed during testing of beam CC-1F, that studs in the east span were beginning to fail in fatigue at about 500,000 cycles and that they were continuously deteriorating with increasing cycles of load application. The installation of a clamp in the east span allowed additional cycles of load to be applied but accelerated the deterioration of the
studs in the west span. The deterioration of the studs in beam CC-1F eventually progressed to the point where the fatigue test was stopped short of the desired 2,000,000 cycles so that a sufficient number of connectors would be left to develop the ultimate load capacity of the beam.

**Deformation of the Continuous Beams**

Deflection under the load point of each beam was measured at intervals throughout the fatigue testing period. Figure 7 summarizes the load-deflection characteristics of the east spans of beams CC-1F and CC-2F. The curves are plotted for the start of testing, for two intermediate cycle levels, and at the end of testing. Also shown for comparative purposes are the theoretical curves for complete interaction and no interaction. Two curves for complete interaction are shown for beam CC-1F. The steeper curve assumes complete interaction throughout the beam (same as for beam CC-2F) and the other assumes complete interaction only in the regions containing studs.

It was apparent after completion of the test program that a small but varying amount of support settlement had occurred during all of the tests partly because of the presence of lead shims at the interior supports. The deflections of the supports were not measured in any of the tests. Some inelastic support settlement occurred during the initial zero-
to-maximum static loading of each beam at the start of fatigue testing. For this reason the "0 cycle" curves in Fig. 7 are plotted so that the unloading curve passes through the origin. Subsequent zero to maximum load-deflection curves therefore show only the effect of further inelastic behavior due to support settlement and other causes as fatigue testing was continued.

Strain Measurements in the Continuous Beams

Strains measured with the electrical resistance strain gages and strains measured using mechanical strain gage points, were used to obtain the distributions of strain throughout the depth of the four continuous beams in both the positive and the negative moment regions. Typical strain distributions in the positive moment regions are shown in Fig. 8a. This figure shows the distribution of strains corresponding to a static load of 60 kips. It can be observed that omitting connectors in the negative moment region of beam CC-1F apparently has little effect on the distribution of strains in the positive moment regions. Similar behavior is reported in Ref. 7. It is also apparent from the figure that the difference in reinforcement and placement of studs in beams CC-3S and CC-4S had no significant effect on the distribution of strains in the positive moment regions of these beams.

Similar comparisons of strains are made in Fig. 8b for a typical section in the negative moment region of the
four continuous beams. The comparison is again made for a static load of 60 kips. It is apparent from the figure that even though beam CC-1F had no shear connectors in the negative moment region, the slab and reinforcement had some effect on the strains in this region. Also the effect of the large amount of longitudinal reinforcement in beams CC-3S and CC-4S can be observed by comparing the strain distribution for all four beams.

Figure 9a compares the location of the neutral axis as a function of applied cycles for typical sections in the positive moment regions of beams CC-1F and CC-2F. Figure 9b makes a similar comparison for beams CC-3S and CC-4S. It can be observed that the number of applications of load had only a small effect on the flexural behavior in the positive moment regions of all four beams.

Figure 10 shows the location of the neutral axis as a function of the applied cycles for typical sections in the negative moment regions. It is apparent from the figure that the slab had cracked in all four beams under the initial application of load and that additional applications of load had only a small effect on the stresses in the steel beams.

**Strain Measurements Near Stud Connectors**

Strain gages were placed on the bottom of the upper beam flange to obtain strain-cycle data from the stud shear
connectors in three regions of each beam as follows: (1) near the exterior supports, (2) in the positive moment region adjacent to the points of contraflexure, and (3) in the negative moment regions.

The strain measurements from these gages were taken during the static tests which were made at intervals during the fatigue tests. The strains obtained at the maximum load were plotted as a function of the applied cycles. Typical results are shown in Figs. 11 and 12. Each figure shows schematically a portion of two steel beams below a strain versus cycle plot for certain studs on the steel beam. The studs are identified as follows:

1. Open circles represents studs from which strain versus cycle data was obtained, studs which were examined visually following fatigue testing, or both.

2. Shaded circles represent studs for which the strain versus cycle curves are plotted immediately above.

3. Circles with strokes through them represent studs which had failed during fatigue testing as evidenced by their separation from the steel beam either before or during the 45° bending test described earlier.

Figure 11 illustrates the response observed over the west exterior supports of three of the four beams. The behavior
over the east supports was similar. It is apparent from the figure that, for beams CC-1F and CC-2F, as fatigue loading was applied to the composite sections, the strains in the flange increased due to increasing flange distortion, indicating that greater load was being carried by the connectors as bond was lost. The strains then leveled out after a few thousand cycles of load application and remained reasonably uniform throughout the remaining portion of the test. The soundness of the connectors over the supports of beam CC-1F is illustrated in Fig. 13 where the photograph taken after fatigue testing shows all to be sound even after bending 45 degrees. It can also be observed from Fig. 11 that the connector failures in beam CC-4S were not apparent from the strain measurements taken near the studs. However, after the slab was removed, the studs were removed from the beam during the bending test. This result was expected in beam CC-4S since the studs in this region were subjected to a high range of shear load in excess of the allowable load range. (See Table 1) All studs over the support in beam CC-4S were removed with one tap of a sledge hammer whereas the three failed studs in beam CC-3S were bent nearly 45° before failure. No strain-cycle data was obtained in this region of beam CC-3S.

Figure 12 illustrates the type of response observed near the east inflection points of the four beams. As was noted
for the regions over the supports, strain increased as the bond was broken and greater load was transferred to the connectors. In addition, it is significant to note that the strains measured in beam CC-1F were nearly twice as great as the strains measured in beam CC-2F. This was because no connectors were provided in the negative moment region of CC-1F and the force in the longitudinal reinforcing steel in that region was being carried by the adjacent connectors in the positive moment region.

As the fatigue loading continued, the strains in the flange of beam CC-1F remained reasonably stable for at least 500,000 cycles. Thereafter, the strains began to decrease as a fatigue crack started to propagate through the base of the stud shear connector. This decrease was particularly severe in the east span of beam CC-1F and nearly the same for all three sets of instrumented studs in this region. The failure of connectors near the point of contraflexure in the east span was rapid as can be observed from Fig. 12.

Figure 12 also shows that virtually all of the studs examined in the negative moment region and near the inflection points of beam CC-3S had failed. These studs were all removed easily during the bending test. This behavior was expected because of the higher than allowable load range in the negative
moment region. Evidently, as studs in this region began to fracture, load was transferred to the studs in the positive moment region closer to the inflection points thus accelerating their rate of failure.

The process of load transfer becomes even more apparent in Fig. 14 when similar studs in the west span of beam CC-4S are examined. The studs between the load points and the inflection points were considerably overloaded. (See Table 1) Therefore, a transfer of load to both of the exterior support regions and to the negative moment region would take place as studs began to fracture. Sufficient capacity existed in the negative moment region to stop complete stud failure near the inflection points. Since no excess capacity existed over the supports, load transfer probably accelerated the stud failures in that region. The response of studs in the west negative moment region of beam CC-2F is also illustrated in Fig. 14. A continuous increase in the apparent strain was noted for the first few hundred thousand cycles as the bond was broken and the slab cracking progressed. In this beam three of the studs fractured after the slab was removed and the studs bent 45 degrees. All six studs examined in Beam CC-1F near the inflection point were fractured.

Photographs of the studs near the east inflection points of beam CC-1F are shown in Fig. 15. The inflection
point passes through the two circular craters at the bottom of the photo which were left by the failure of studs 15 (left) and 16 (right). These studs remained imbedded in the portion of concrete slab which was removed. Studs 17 and 19 (left) and 18 and 20 (right) are shown beside their former positions after they were removed by hand. Since these studs were nearly completely fractured from the beam after the slab was removed, it is probable that the high strain readings observed at the end of the test were caused by the dowelling of the failed stud in the rather deep crater that was taken from the beam flange. A typical view of the fracture surface of one of these studs is shown in Fig. 16. The fatigue fracture surfaces can easily be seen.

**Slip Measurements**

Slip measurements were taken at the exterior supports of each beam and at various locations in the negative moment region. Measurements were started in the negative moment region of beam CC-1F after about 1,000,000 cycles of loading.

Previous studies indicated that the range of slip yields some information on the fatigue failure of connectors (1,5). Figure 17 is a bar graph indicating the range of slip and direction of the range of slip between 0 and 60 kips at various cycles of load application for beams CC-1F and CC-2F. It is apparent that after bond had broken in both beams
the range of slip at the exterior supports changed very little. In the negative moment region of beam CC-1F, the range of slip was much greater than at the exterior supports and at least twice the range of slip in the negative moment region of beam CC-2F. The same is true also at the inflection points in both beams. This is in agreement with the observed levels of shear connector strain shown in Fig. 12. Since the range of slip was not recorded at the inflection points of beam CC-1F until after obvious stud failures in that region, it is not known whether the large ranges of slip observed in beam CC-1F occurred after stud failure or was present from the beginning of the fatigue test.

Cracking of Slabs in the Negative Moment Regions

All slabs were relatively free of cracks at the beginning of each test but cracked during the initial static loading of the beams. A few additional small cracks generally appeared during the fatigue tests, except in beam CC-1F where most of the cracking developed as fatigue testing progressed. The distribution of slab cracking is shown schematically in Fig. 18. Crack widths were measured on beam CC-3S, under a static load of 60 kips following the fatigue test, and are shown in Fig. 18(c). The average width along a crack is shown as well as the maximum width which is shown in brackets. The average crack widths shown in Figs. 18 (a), (b), and (d) were estimated, based on the known widths in beam CC-3S.
During the initial static loading of beam CC-1F to 60 kips relatively large cracks occurred about 8 and 18 inches on either side of the center support. Little or no cracking was observed elsewhere. This was expected since flexural conformance in this region due to bond would result in larger cracks near the center support. The cracks were approximately perpendicular to the beam axis and increased in width as fatigue testing progressed. Additional smaller cracks also appeared throughout the rest of the negative moment region of beam CC-1F as fatigue testing continued. These cracks appeared at approximately 12 inch intervals near the inflection points and at 6 inch intervals near the center support. Since the crack width did not vary appreciably through most of the negative moment region except over the support, it seems that the tensile force in the slab was reasonably uniform in this region. Many additional cracks would occur during fatigue because of the decrease in flexural conformance in this region as bond was lost and as studs near the inflection points failed.

Beam CC-2F had connectors placed in the negative moment region except for a 22 in. length on either side of the interior support. The crack pattern was substantially different in this beam. Cracking was limited to a region of approximately 3 ft. on either side of the support. The cracks in
the regions with connectors were very small and remained small throughout the test. In the region without connectors, several large cracks formed with the largest being directly over the support.

As is apparent from Fig. 18, the crack widths in beams CC-3S and CC-4S were substantially reduced with the increased area of longitudinal reinforcement. In beam CC-3S, cracks extended 4 and 5 ft. on either side of the center support whereas in beam CC-4S, cracks extended only about 3 ft. on either side of the support.

**ANALYSIS OF TEST RESULTS**

**Stresses and Bending Moments in Continuous Composite Beams**

Figures 9 and 10 show that reasonably good agreement can be obtained by assuming that all beam sections, including the negative moment region of beam CC-1F, have complete interaction. It is readily apparent that the steel beam section of beam CC-1F is interacting with the longitudinal reinforcement in the negative moment region. This behavior should be expected since considerable tensile force will be developed in the longitudinal steel due to the rotation of the beam cross-sections at each inflection point. Since no shear transfer can take place between the slab and the beam after bond has been broken (except for frictional
flexural conformance cannot exist in the negative moment region of beam CC-1F. A higher degree of flexural conformity was present in beam CC-2F, but was less than the assumption of complete interaction would require.

Figure 19 compares the theoretical and experimental bending moment distributions in beams CC-1F and CC-2F for a load of 60 kips. The change in the experimental bending moments from zero cycles to the end of each fatigue test was relatively small, therefore only the distribution of moments at zero cycles was plotted in this figure (solid curve). A small loss of interaction was obtained during the fatigue tests as expected.

Figure 19 again confirms an earlier observation that beams CC-1F and CC-2F were carrying load in a similar manner, even though no connectors were provided in the negative moment region of beam CC-1F. As discussed earlier, this behavior was a result of the considerable magnitude of tensile forces induced in the longitudinal reinforcement throughout the negative moment region of beam CC-1F due to the anchorage forces which were produced at the inflection points. Although similar static load behavior of the two beams is indicated in Fig. 19, the dynamic response of beam CC-1F was decidedly poorer than that of beam CC-2F. It was difficult to maintain the maximum dynamic load during the test of beam
CC-1F because of the uneven deflection characteristics of each span, especially in the vicinity of 1,000,000 cycles of load application. This was undoubtedly due to the rapid deterioration of studs in the region of the high anchorage forces which developed near each inflection point.

A comparison of the theoretical and experimental bending moment curves for all four beams indicated good agreement at zero cycles with a small loss of interaction evident at the end of the fatigue tests. The loss of interaction appeared to be the least in beams CC-1F and CC-2F and a maximum in beam CC-4S.

**Slab Force Resisted by Shear Connection**

In composite beams, the degree of interaction and flexural conformance is determined by the amount of slip between the concrete slab and the steel beam. A high degree of flexural conformance can be maintained only if sufficient shear connection is provided to minimize the slip. Interaction and flexural conformance are of particular interest in the negative moment regions of continuous composite beams. To help evaluate the degree of interaction in beams CC-1F and CC-2F, the force in the slab at the inflection points and near the center support were computed from the measured strains in the steel beams. Computations of the tensile force in the slab based on the strain data from the reinforcing steel over the
support were not as reliable because of the influence of moment gradient and slab cracking. Figure 20 shows the computed slab forces near the center support of beams CC-1F and CC-2F as a function of the applied cycles of load. Also shown for comparison is the theoretical tensile slab force based on three simplifying assumptions. Assumption (c) considers the tensile force in the longitudinal reinforcement computed from the rotations at the inflection points.

The figure show that the slab force over the support of both beams rapidly decreased during the first 200,000 cycles of loading. This was probably due to loss of interaction as bond was destroyed, as well as slab cracking. In beam CC-1F, the initial slab force (force in the longitudinal reinforcing) was nearly equal to the theoretical value for a cracked section with complete interaction, but rapidly decreased to a level somewhat below the predicted value [assumption (c)]. However it was observed from other data that at the inflection points of beam CC-1F the slab force was virtually as predicted [assumption (c)] at least up to the observed initial failure of connectors. Since frictional forces can account for the small difference between the measured and predicted force near the support, it is apparent that, neglecting friction, the slab force is nearly uniform over the entire negative moment region when no connectors are placed in that region.
The slab force in beam CC-2F maintained a level in the region near the interior support somewhat greater than that in beam CC-1F. Because of the presence of shear connectors, a higher initial slab force was observed (Fig. 20) until the slab was fully cracked. The slab force decreased in both spans of beam CC-2F at about the same rate. The force approximately stabilized at a value somewhat above the predicted value [assumption (b)] after about 200,000 cycles. Other data indicated that at the inflection points of beam CC-2F the slab force approached zero, which flexural conformance would require. It is obvious then that for beam CC-2F shear transfer was taking place between the slab in the negative moment region and the steel beam as a result of the stud shear connection in that region.

Similar behavior was observed in the negative moment regions of beams CC-3S and CC-4S. However, the slab forces were substantially greater in these two beams because of the increased amounts of longitudinal reinforcing steel. The degree of interaction was also somewhat greater in these beams because of the greater number of shear connectors in the negative moment region.

The effect of stud failures near the inflection points of beam CC-1F on the slab forces at the center support can also be observed in Fig. 20. The slab forces were
Daniels, Fisher

rapidly changing at about 1,000,000 cycles. The clamp which was in place from 1,074,900 cycles to 1,375,500 cycles resulted in a readjustment of the slab forces so that they were again reasonably uniform.

It is apparent from the fatigue behavior of the four test beams and the comparison shown in Fig. 20 that shear connectors are required to resist the slab force in the negative moment region of all continuous composite beams which have continuous longitudinal reinforcement.

**Forces on Stud Connectors**

It was also of interest to examine the forces to which the shear connectors were subjected during the progress of the tests. Of particular interest were those connectors at the ends of the beams, in the positive moment regions adjacent to the points of contraflexure, and in the negative moment region. Figure 20 showed that bond failure between the slab and the beam as well as slab cracking took place in the negative moment region. The slab force necessarily had to be resisted by the connectors alone when they were present. In the end portions of each beam bond failure started at the end of the member and progressed toward the load points. In the positive moment regions adjacent to the points of contraflexure bond failure progressed from the points of contraflexure toward the load points.
The average force per connector was computed as the compressive force in the slab at a strain gage location divided by the number of connectors between that location and the end of the beam or the point of contraflexure, whichever was applicable. Table 5 summarizes the forces on the studs in the west spans of each beam at various cycles of load application. The forces in the east spans were similar. The applied load was 60$^k$ for beams CC-1F, CC-2F, and CC-3S, and 70$^k$ for beam CC-4S. A comparison is made between the shear forces computed from strain data with the values of shear force computed according to elastic theory for horizontal shear. In general, the agreement could be considered good, taking into account the assumptions made.

In beam CC-1F, since no connectors were provided in the negative moment region to resist the slab force, it was resisted only by the shear connectors in the positive moment regions adjacent to the points of contraflexure. The test showed that at least three pairs of studs adjacent to the points of contraflexure were carrying the additional force. Qualitative strain-cycle measurements were not taken on other studs in these regions, so it was not known how many other studs adjacent to the points of contraflexure actually resisted the additional slab force transmitted by the longitudinal slab steel in the negative moment region. If one assumes this additional force to be aver-
aged over all the connectors between the load point and the point of contraflexure, the shear load varied from approximately 5.70 to 5.90 kips per stud as shown in Table 5. If only half the connectors were assumed to carry this load, then they would be subjected to an average shear of about 7 kips per stud.

Figure 21 compares the design cumulative resistance of the shear connectors in beam CC-1F and CC-2F with the measured slab force at various locations along the beams. The comparison is made at 2,000,000 cycles with a load of 60 kips. It is apparent that connectors in beam CC-2F were subjected to forces that very closely correlated with their design resistance. The figure also shows that in the negative moment region of beam CC-2F the tensile force in the slab was being adequately transferred into the beam by the shear connectors. At the points of contraflexure little slab force was present, confirming that the connectors in the negative moment region were effective. Similar behavior was observed in beams CC-3S and CC-4S.

In beam CC-1F, this was not the case. The slab force was approximately the same at the points of contraflexure and near the center support. This confirms again the previous discussion on the behavior in the negative moment region. It is apparent that the longitudinal slab reinforcing was acting like tendons in an unbonded post-tensioned beam, with the reinforcing being anchored in the region of the inflection points. Consequently,
the studs near the inflection points were subjected to shear forces considerably higher than those used in the designs. This undoubtedly contributed to the early failure of those shear connectors in beam CC-1F.

**Fatigue Strength of Stud Shear Connectors**

It is realized that the method of detecting connector failure is not exact but it is believed to give conservative results. Table 6 summarizes all the test data to show the cycle life for the connectors in the five regions of interest for each test beam. Also shown is the average stress on the connectors in a given region during the indicated cycle life. Failures were observed in all four test beams.

The test data summarized in Table 6 was compared in Fig. 22 with the S-N curve developed in Ref. 3. Each failure point (shaded circle) represents the average stress versus observed cycle life, for from 6 to 24 studs. Where no failures were observed the points were plotted as runouts (open circle with arrow). As was noted in Ref. 3, pushout tests provide a lower bound of the fatigue strength. Since the mean S-N curve shown in Fig. 10 of Ref. 3 was based on pushout tests, these beam test results were expected to exhibit slightly greater cycle lives. Most of the test results shown in Fig. 22 verify this behavior since they lie between the mean curve and the upper limit of dispersion. Except for one failure point representing
the early failures near the east inflection point of beam CC-lF, each failure point lying below the mean curve in Fig. 22 represents failures detected only by the bending test. No failures were apparent from the flange distortion gage readings for these studs. Thus, these points represents a conservative estimate of cycle life.

**Comparison of Beam Performance**

The four continuous composite beams in this study provide several direct comparisons of beam performance. Two major variables were evaluated: (1) The placement of connectors in the negative moment region. (2) The effect of increasing the amount of longitudinal steel in the negative moment region.

The placement of connectors in the negative moment regions of beams CC-2F, CC-3S, and CC-4S provided better flexural conformance, better dynamic response of the beam, and more uniform beam behavior. The performance of beam CC-lF was decidedly poor. Premature fatigue failures were detected near the points of contraflexure and the general response of the beam to cyclic loading was very poor. The two spans of this beam were observed to behave differently under dynamic load. Since the dynamic behavior of CC-2F was considerably improved, this was undoubtedly due to the presence of shear connectors in the negative moment region of beam CC-2F, since all other aspects of CC-lF and CC-2F were identical.
The slab cracking patterns in beams CC-1F and CC-2F also differed appreciably. In beam CC-1F the cracks were of about equal width throughout the negative moment region, confirming that the force in the longitudinal reinforcement was reasonably uniform throughout that region. Although beam CC-2F had connectors designed to transmit the force in the longitudinal reinforcement, they were not continuous throughout the negative moment region partly because only a few were required but mainly because it was desirable to shift them toward the points of contra-flexure in order to prevent a premature fatigue failure in the beam flange over the center support. As a result, large cracks occurred in the short length in which the connectors were omitted. As bond was destroyed and the slab force was transferred to the connectors in the negative moment region the crack widths decreased somewhat as additional smaller cracks appeared closer to the inflection points. In both beams CC-1F and CC-2F the maximum crack widths exceeded the limits suggested in Ref. 8 for cracks in reinforced concrete bridges at the service load level.

Beams CC-3S and CC-4S had substantially more longitudinal reinforcement in the negative moment region. This additional reinforcement greatly increased the flexural conformance of the composite beams. In addition, slab cracking behavior was greatly improved over that of beams CC-1F and CC-2F. There was not much difference in the behavior of beams CC-3S and CC-4S with respect
to dynamic response, flexural conformance, and crack width and distribution. Hence the larger increase in longitudinal reinforcement in beam CC-4S provided virtually no improvement in behavior over that of beam CC-3S.

Comparison of Test Results with Design Recommendations

Reference 3 suggested that shear connectors are needed in the negative moment regions to provide resistance to the force developed in the reinforcing steel. Also, elastic theory assuming complete interaction was recommended to evaluate the horizontal shear resisted by the shear connection. The present study has confirmed these recommendations. It has shown clearly that shear connectors are required to resist the force developed in continuous longitudinal reinforcement steel in the negative moment regions. When they are omitted, the response of the structure will be poor and fatigue failure of connectors adjacent to the points of contraflexure will occur at a substantially lower number of cycles than that assumed in the design. This study also confirmed that elastic theory can be used to evaluate the horizontal shear transferred by the shear connectors. Only the cracked section of the concrete slab is effective. Thus the statical moment of the composite section need only consider the longitudinal reinforcing steel in the slab. All longitudinal reinforcing steel in the slab cross-section was observed to be
Daniels, Fisher

effective in these tests. It would appear, then, that all longitu-
dudinal reinforcement should be taken into account when ascer-
taining the magnitude of the slab force which must be resisted, 
at least up to the width-to-depth ratio used in this study.
The results of fatigue tests of four continuous composite steel-concrete beams have been presented in this paper. Each beam had two equal spans of 25 ft. and consisted of a 60 in. by 6 in. reinforced concrete slab connected to a 21W62 A36 steel beam with 3/4 in. x 4 in. headed steel stud shear connectors. Two beams were designed for 2,000,000 cycles of load application; two were designed for 500,000 cycles of load. A pulsating concentrated load was applied to each span by two hydraulic jacks. The load varied from near zero to a maximum approximately equal to the service load for each beam. The loading rate was constant for all beams at 250 cycles of zero to maximum load per minute.

Two beams were designed according to the current AASHO Bridge Design Specifications except for the shear connection which was designed in accordance with the procedure recommended in Ref. 3. The shear connectors were left out of the negative moment region of one of the beams so that a comparison of the two beams could be made.

The other two beams were also designed in accordance with the AASHO Specifications and the recommendations of Ref. 3. However, each beam had substantially greater amounts of longitudinal reinforcement in the negative moment region.
The basic variables investigated in this test program were: (1) the effect of stud shear connectors in the negative moment region on the fatigue behavior of the test beams, and (2) the effect of increased amounts of longitudinal reinforcing steel in the negative moment regions.

The following conclusions were drawn from an analysis of the test results:

1. Shear connectors are required to resist the force in the longitudinal slab reinforcement in the negative moment regions of continuous composite beams. The amount of shear connection required depends upon the percentage of longitudinal reinforcing steel in that region.

2. More longitudinal reinforcement in the negative moment regions of continuous composite beams than presently allowed by the AASHO Specifications appears to be desirable in order to control the number and widths of slab cracks as well as to improve interaction and flexural conformance in that region. It was evident from the test results that this will also improve the deflection characteristics and overall structural behavior of the continuous composite beam under dynamic loads.
3. Further study is required to evaluate the effects of stud placement, cover plates prestressing and haunching in the negative moment regions of continuous composite beams, as well as to determine the optimum reinforcement required for adequate crack control.
ACKNOWLEDGMENTS

The study described in this report was part of an investigation on composite beams that was conducted at Fritz Engineering Laboratory, Department of Civil Engineering, Lehigh University. L. S. Beedle is Director of the Laboratory. The project was financed by the New York Department of Public Works, the Department of Commerce - Bureau of Public Roads, Nelson Stud Division of Gregory Industries, Inc., KSM Products Division of Omark Industries Inc., Tru-Weld Division of Tru-Fit Screw Products Inc., and Lehigh University.

The writers are particularly indebted to R. G. Slutter for his advice and help in the planning and conduct of these tests. Sincere thanks are also due Noriaki Yoshida and James O. Armacost III for assistance in the conduct of several of the tests and for aid in reducing and analyzing the test data; to Messrs. K. R. Harpel and C. F. Hittinger and their staff at the Fritz Laboratory for their work in preparing the test set-up and instrumentation; also to R. N. Sopko and his staff for preparing the figures, and to Mrs. Shirley Labert for typing the manuscript.

</table>

1 Ratio of number of studs failed to number of studs examined.

2 The force in the negative reinforcement was distributed over all the studs in the interior positive moment regions. Distribution of force over 1/2 the studs would increase the stress ranges to 15.33 and 14.70 ksi respectively for the W. and E. interior positive moment regions.
